FINAL ASSIGNMENT DUE ON NOV 30

SYSTEMATIC REVIEW & META-ANALYSES

SYSTEMATIC REVIEW:
SUMMARY OF THE AVAILABLE EVIDENCE

META-ANALYSIS:
STATISTICAL METHODS TO SYNTHESIZE FINDINGS

GOOD SRMAS
INTERESTING BUT ADDRESSABLE RESEARCH QUESTION
RIGOROUS AND TRANSPARANET METHODOLOGY
SETTLES CONTROVERSIES AND DEFINE NEW HYPOTHESES

A GOOD SRMA = SUBSTANTIAL WORK
RELATIVELY HIGH PAYOFF IF WELL DONE

IDENTIFICATION OF A GOOD QUESTION

A PRIORI 'INSIGHT' INTO THE LITERATURE

ITERATIVE APPROACH TO DEFINE/SPECIFY THE GOALS

STUDY SCREENING + SELECTION

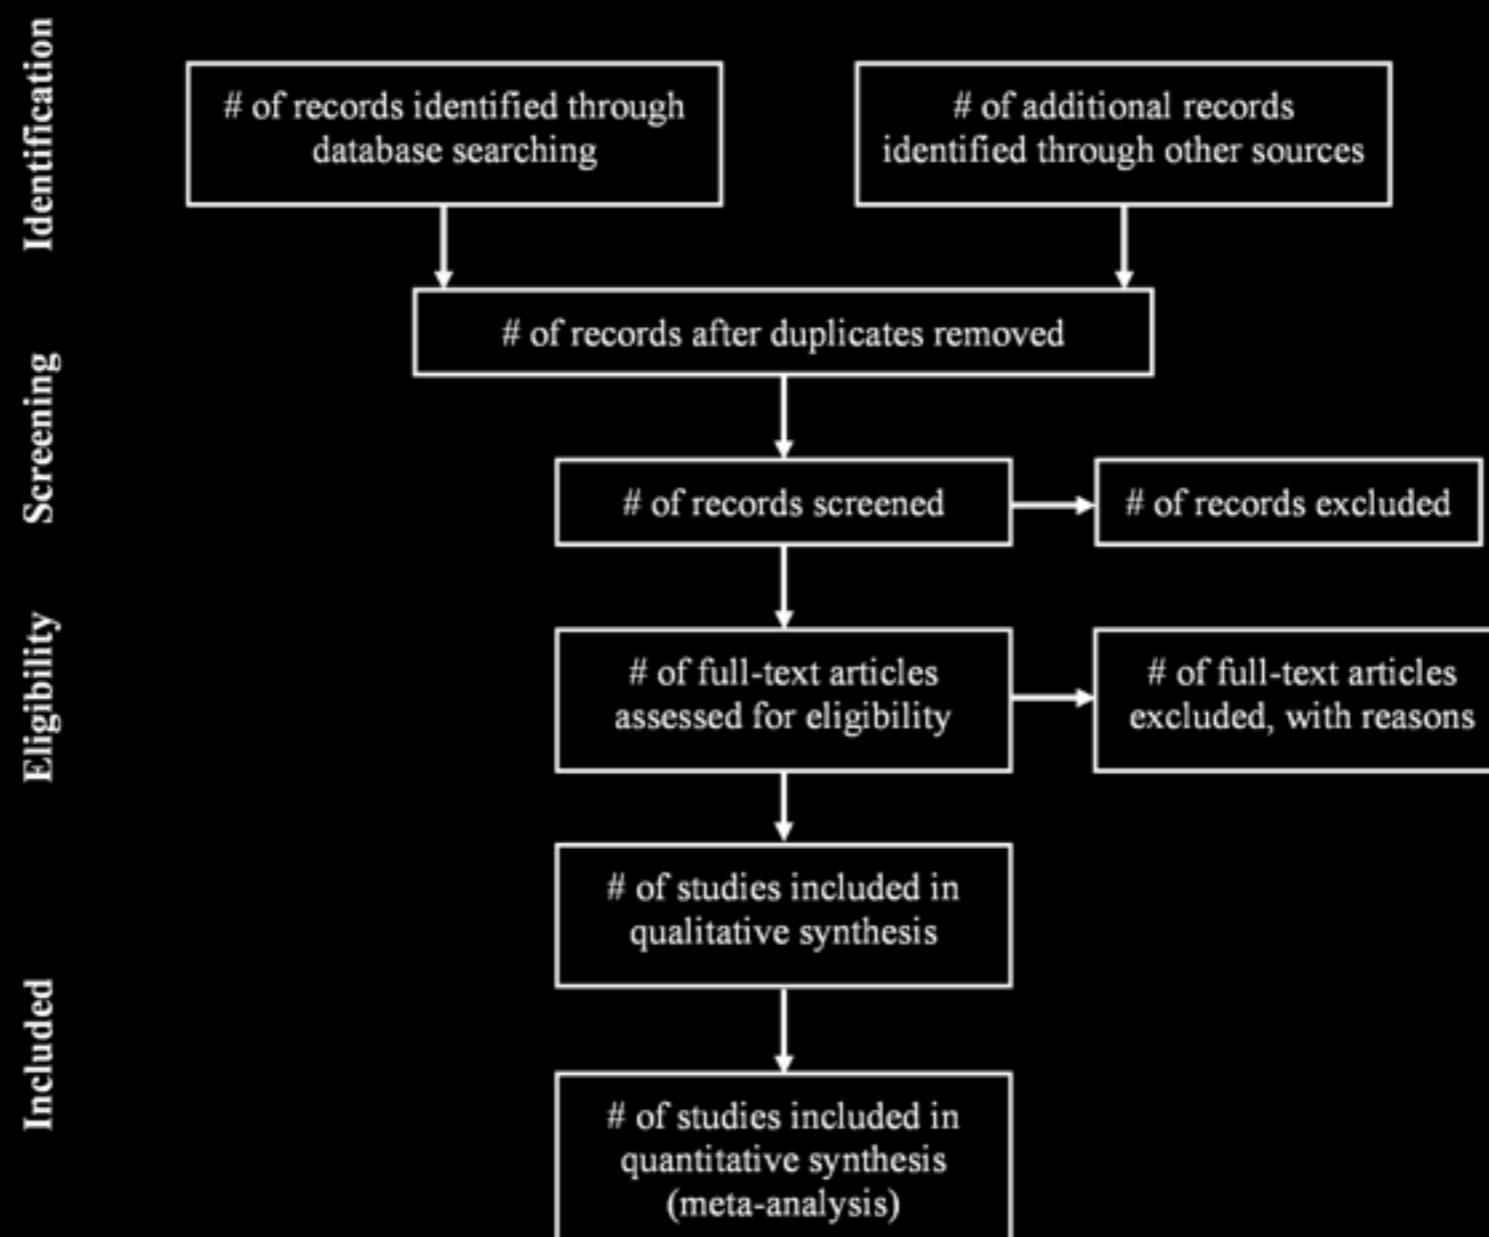

OVERALL GOAL:

REDUCE HETEROGENEITY THAT CANNOT BE MODELLED

GIVE OVERVIEW OF PREVIOUS STUDIES

EVALUATE BIAS (GARBAGE IN - GARBAGE OUT)

STUDY IDENTIFICATION: THE PRISMA GUIDELINES

COLLECTING EFFECT SIZE MEASURES + TRANSFORMING THEM

CORRELATION COEFFICIENTS

T-STATISTICS

ODDS-RATIOS

...

CAN BE CONVERTED INTO COMMON UNIT

FIXED VS RANDOM EFFECTS

REMEMBER THE GLMS IN WEEK 2?

FIXED EFFECT MA:

ASSUMES THAT TRUE EFFECT DOES NOT VARY BETWEEN STUDIES
AND THAT VARIATIONS IN OBSERVED EFFECTS ARE DUE TO SAMPLING ERROR

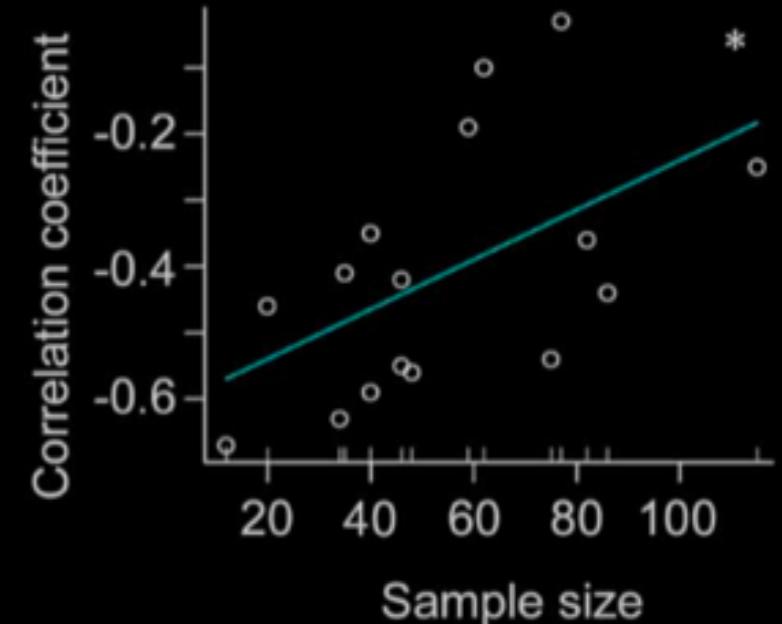

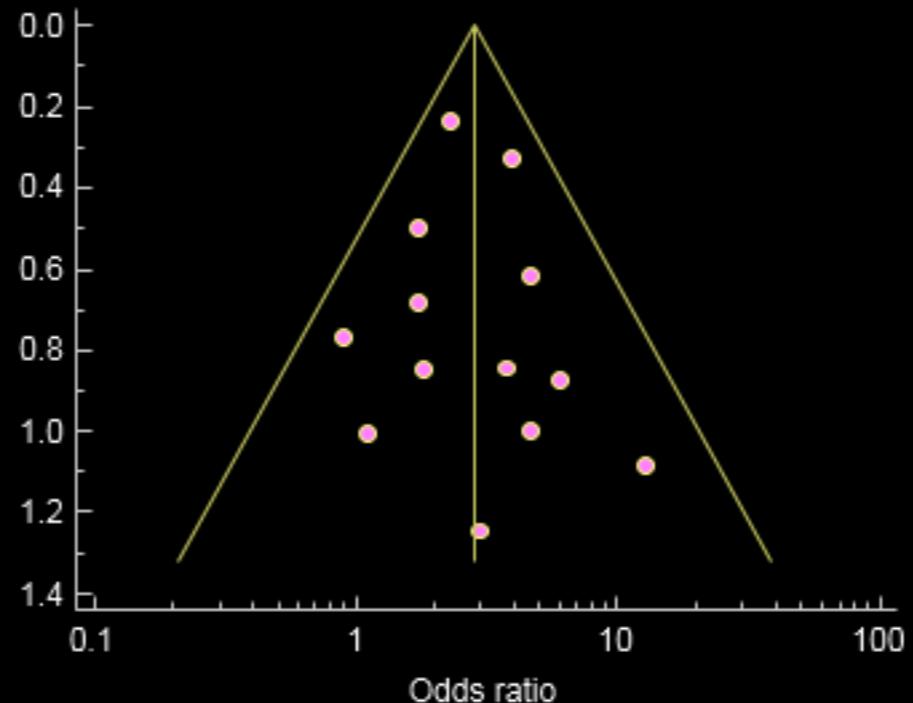

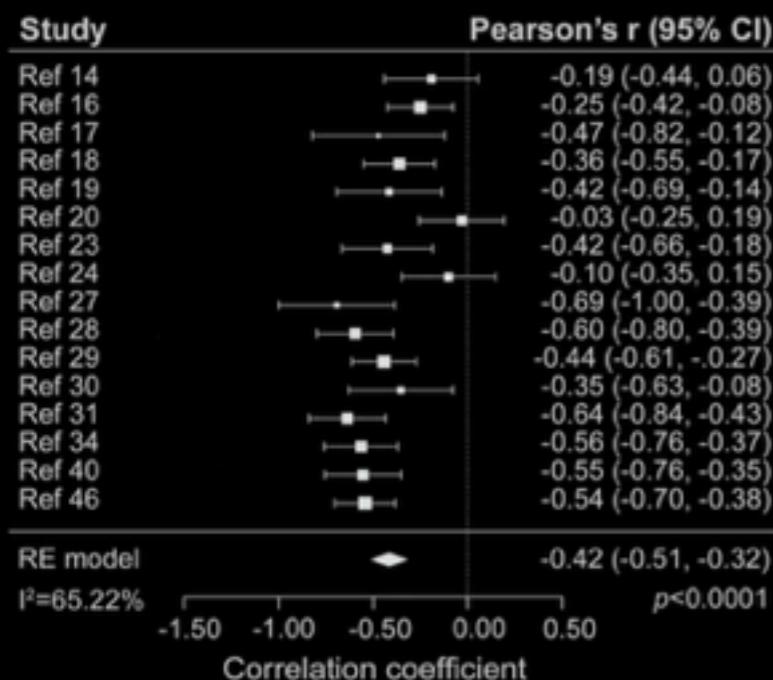

RANDOM EFFECTS MA:

ASSUMES THAT TRUE EFFECT DOES VARY BETWEEN STUDIES
AND THAT VARIATION IN EFFECTS ARE DUE TO SAMPLING ERROR

RANDOM EFFECTS GENERALLY RECOMMENDED
BUT OFTEN GOOD TO RUN BOTH

GingerALE Version 2.3.6

GingerALE is the BrainMap application that is used to perform an ALE meta-analysis on coordinates in Talairach or MNI space. GingerALE can also be used to convert coordinates between MNI and Talairach spaces using the [icbm2tal](#) transform.

The ALE meta-analysis method was initially developed by Peter Turkeltaub ([Turkeltaub et al., 2002](#)). This method of meta-analysis was adopted by BrainMap in 2003. Several modifications have been made to the ALE algorithm since then, and the current version of our software is reported in [Eickhoff et al., 2009](#).

All output files are written in [NIfTI \(.nii\)](#) format. The input for a meta-analysis can be a set of coordinates in Talairach or MNI space, or a set of

Meta-analysis of all disorders

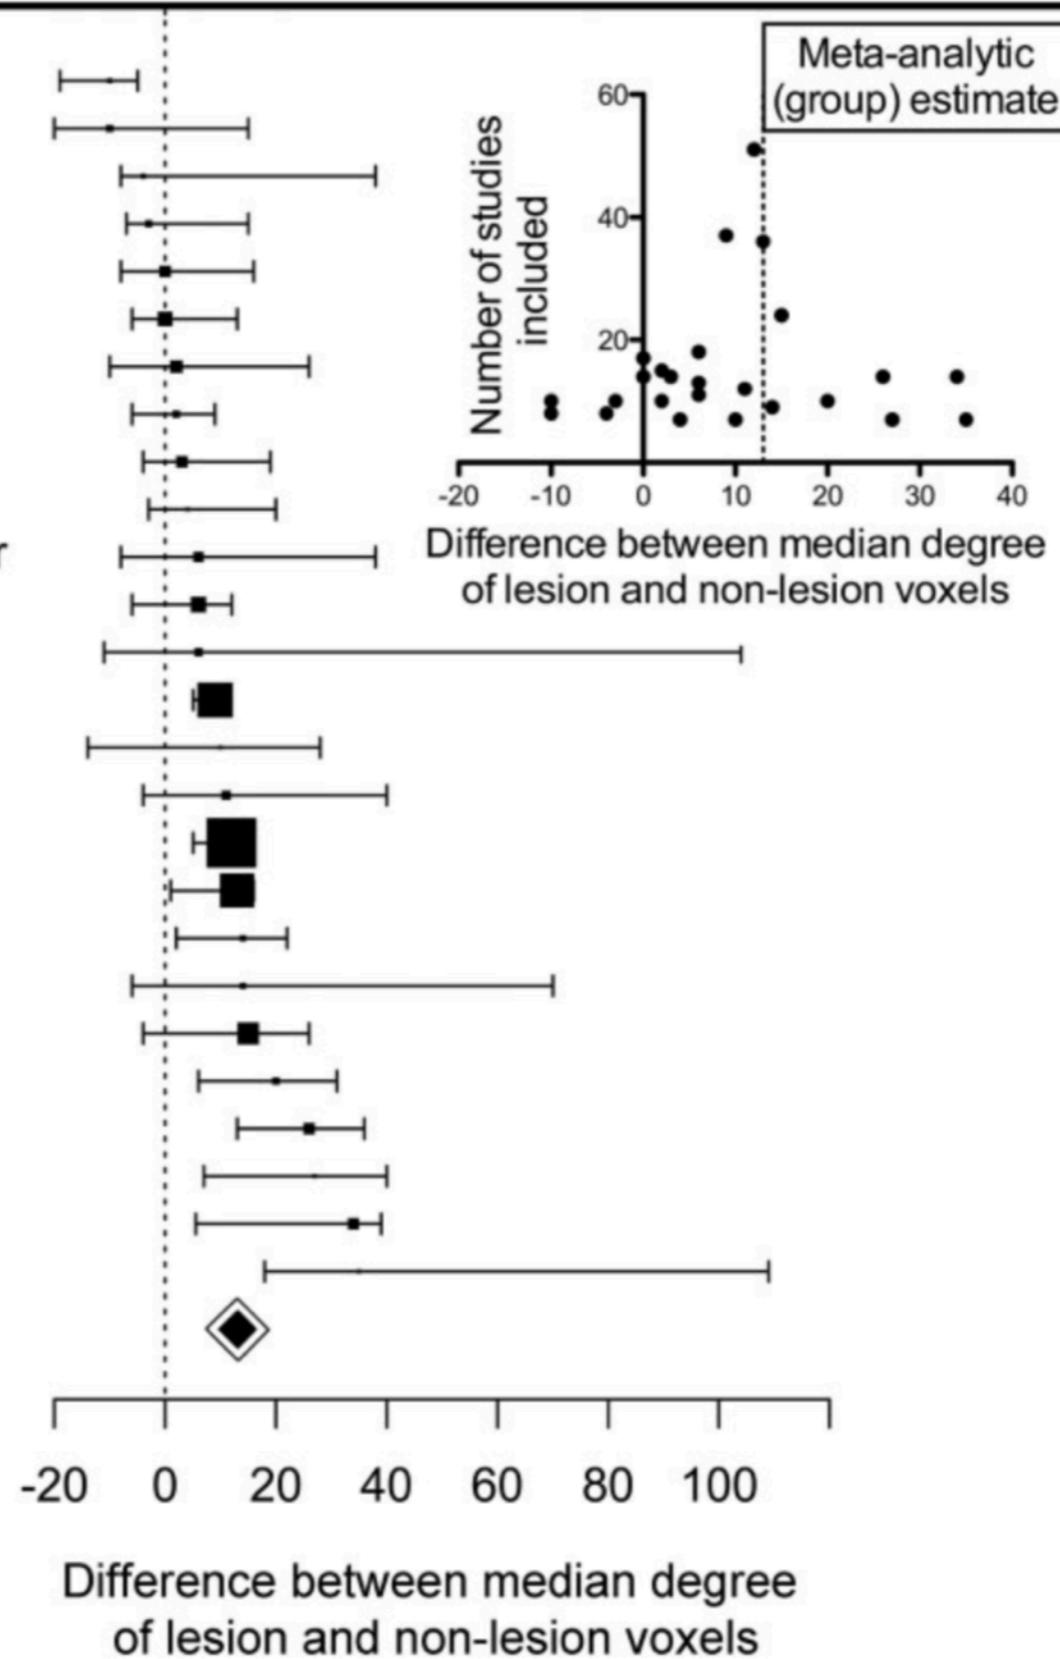

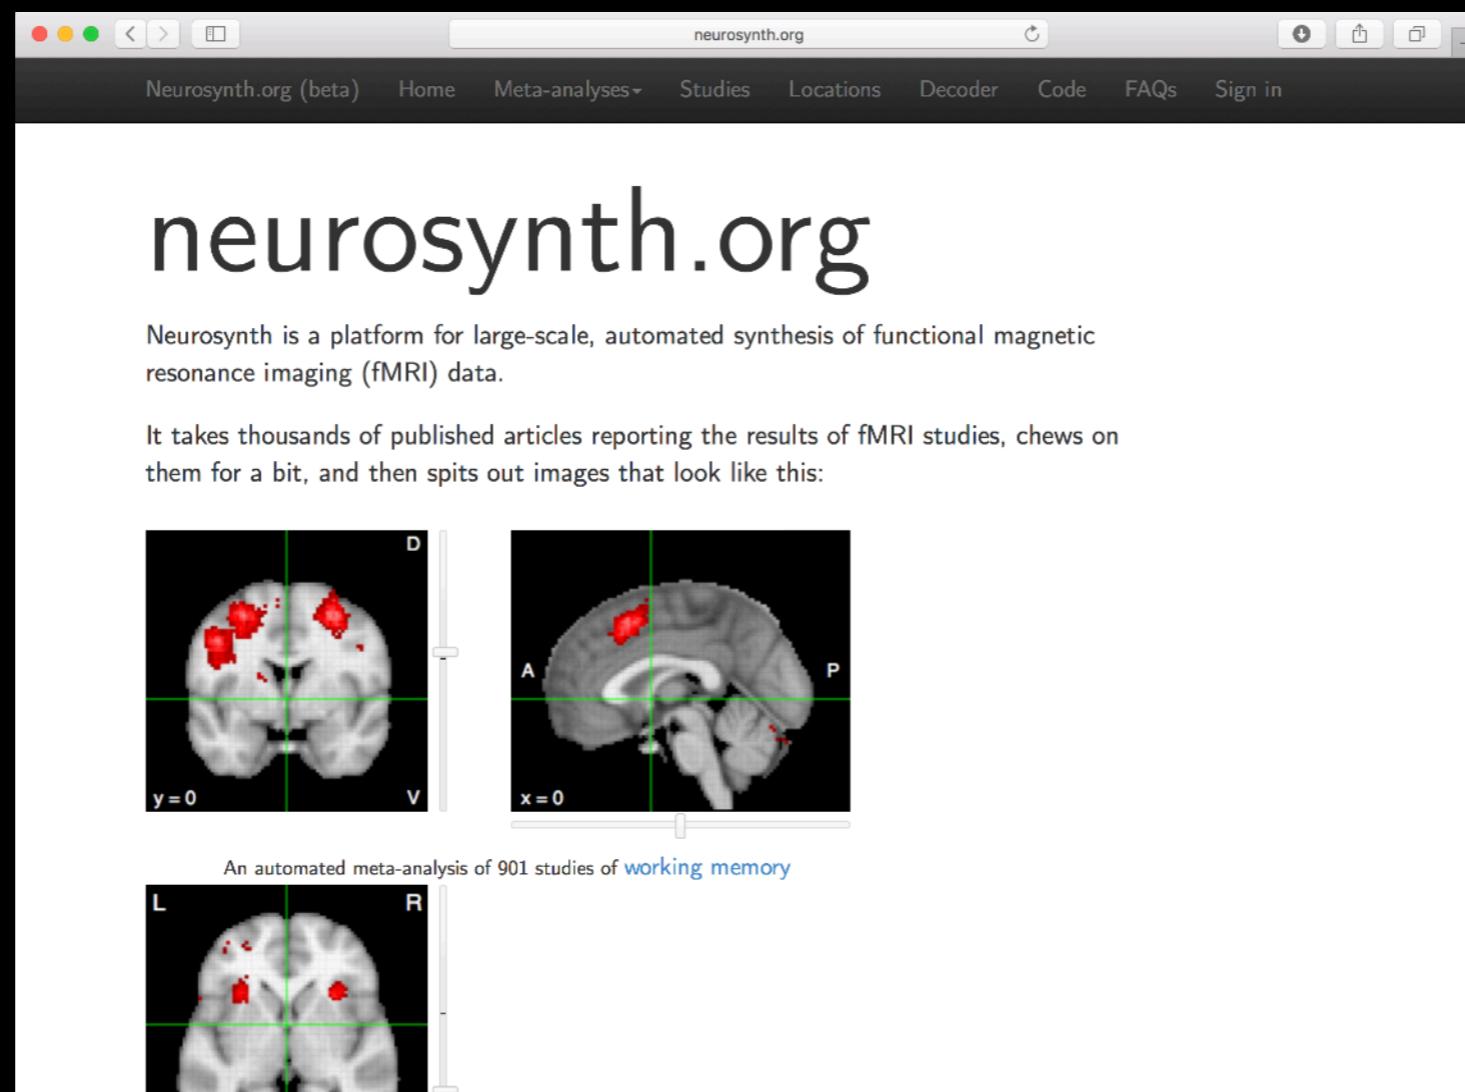

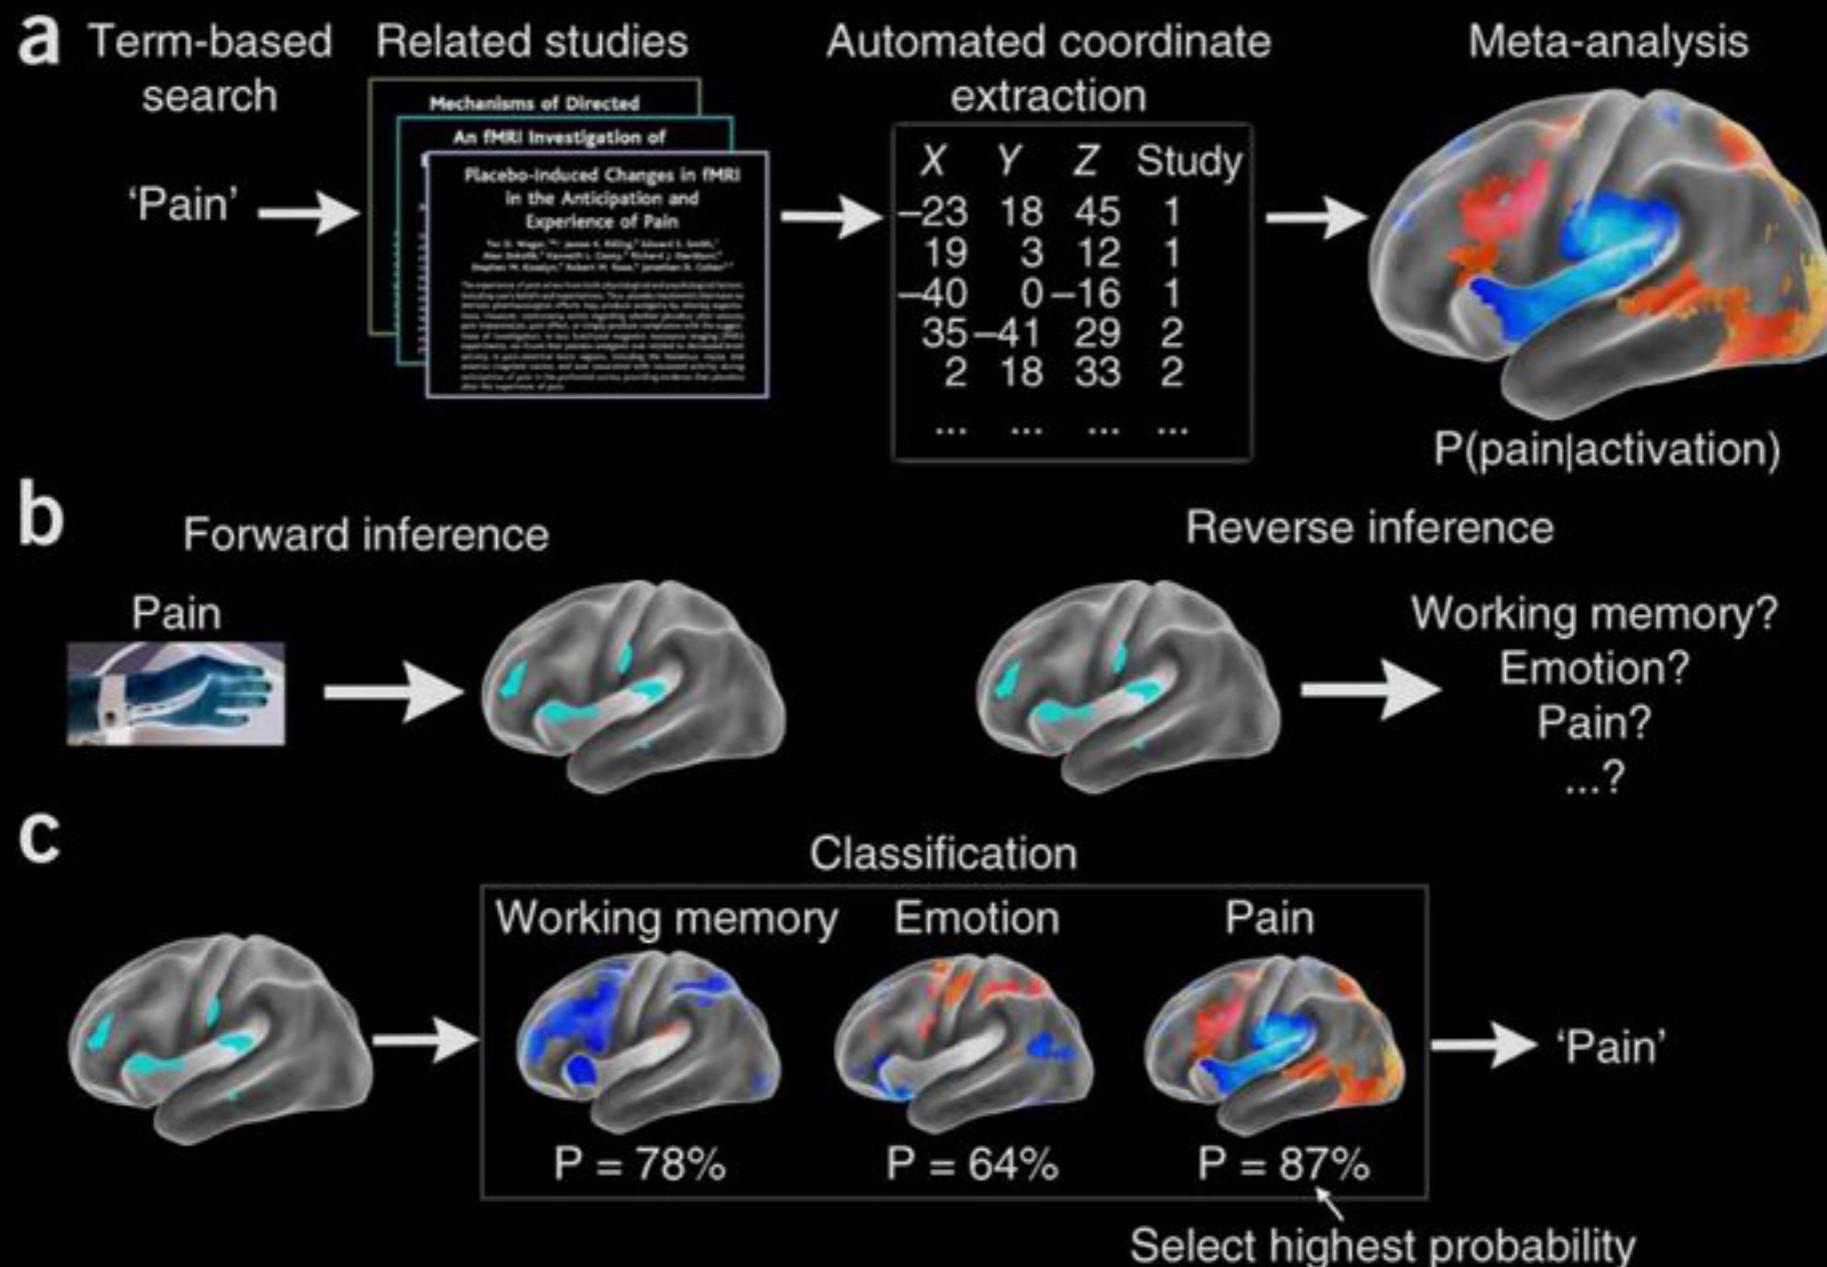

Figure 6 Hub concentration of lesions is common to many specific brain disorders. For each of 26 disorders, box plots represent the difference in median degree of lesion voxels versus non-lesion voxels with a bootstrap 95% CI; the size of the box is proportional to the number of primary studies in the MRI literature. Small inset plot shows the relationship between sample size and difference in median degree for every study. Note that results from individual disorders are symmetrically distributed around the meta-analytical summary of all disorders, with a larger variance observed for disorders represented by fewer studies.

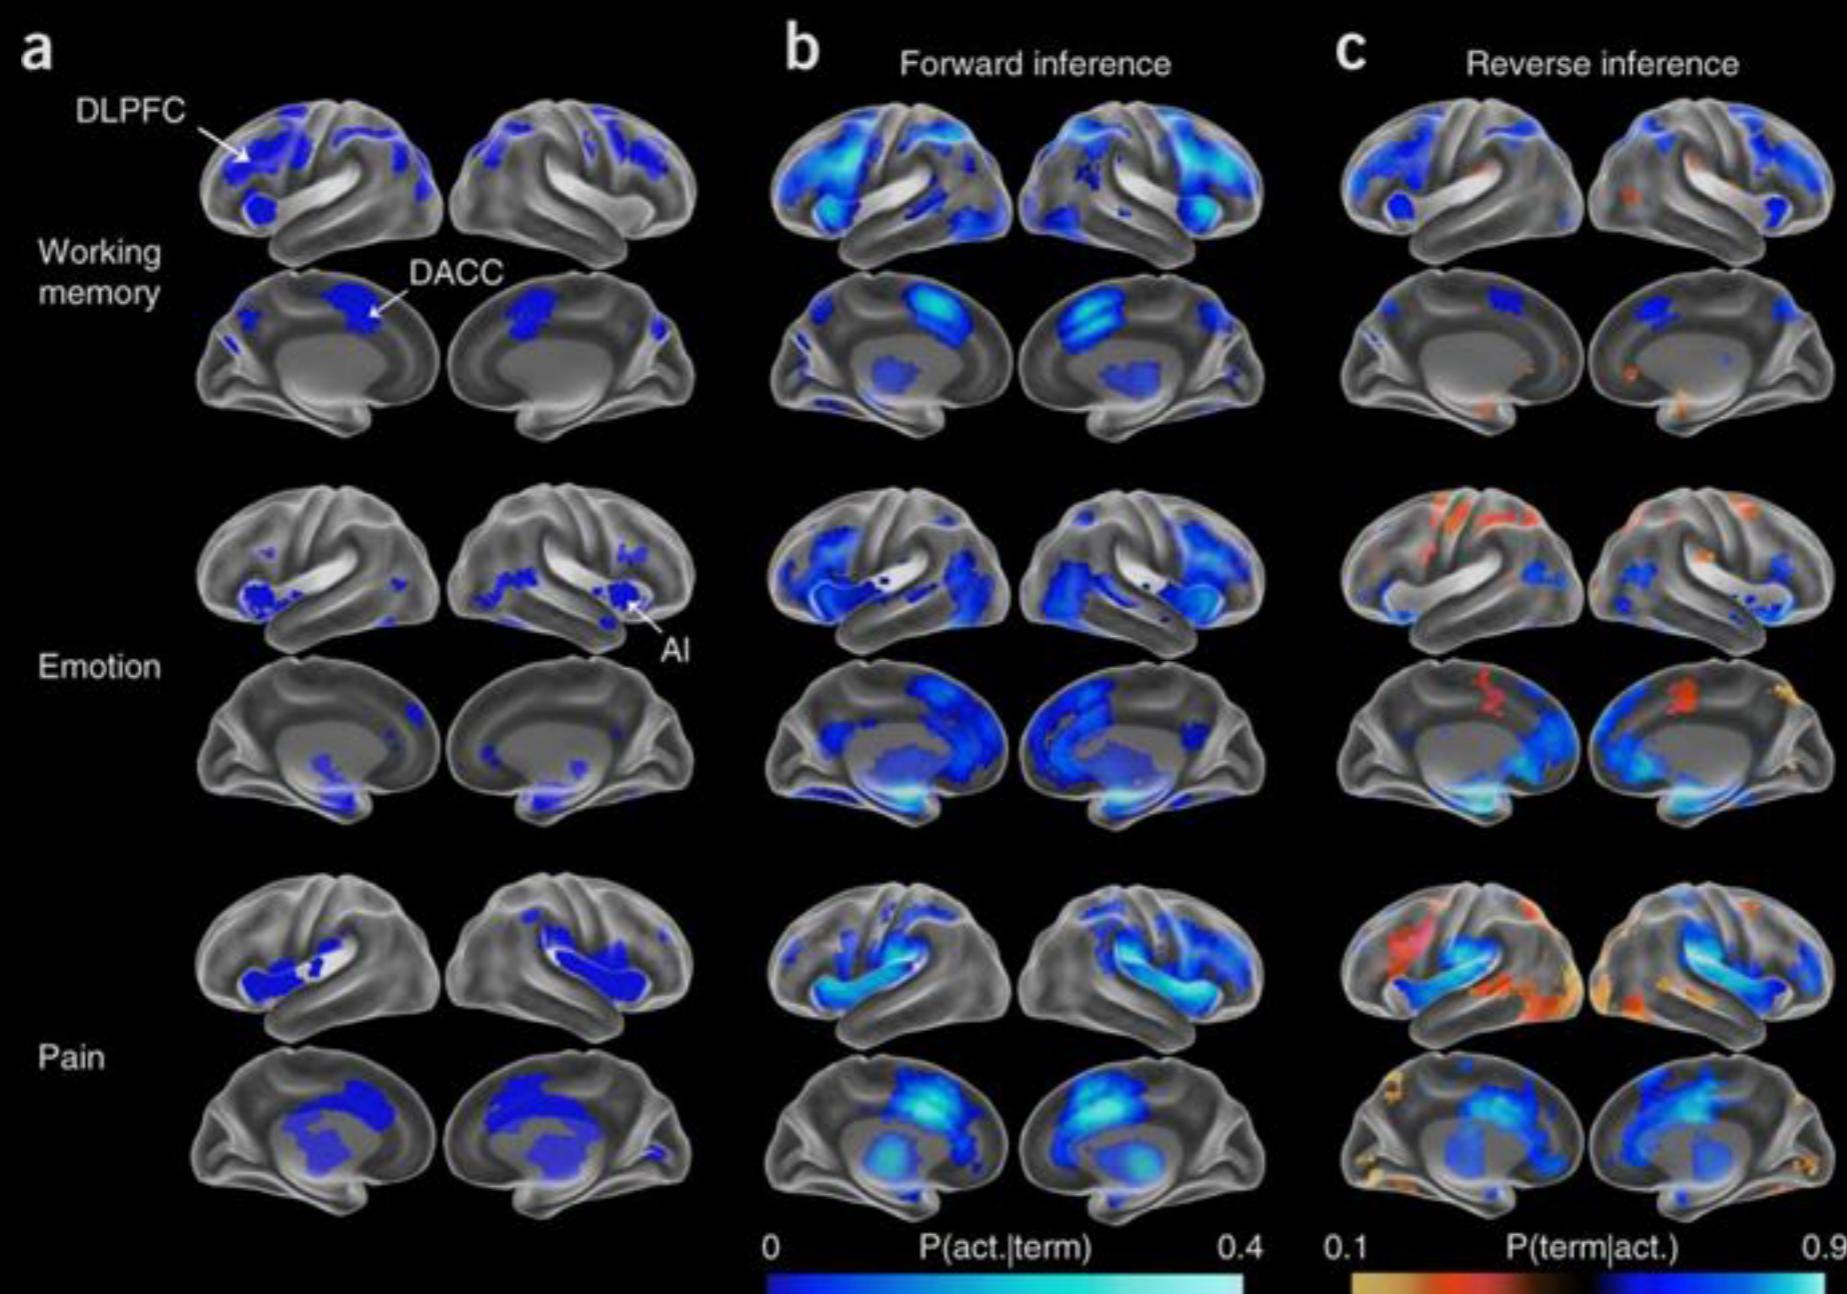

NEUROSYNTH

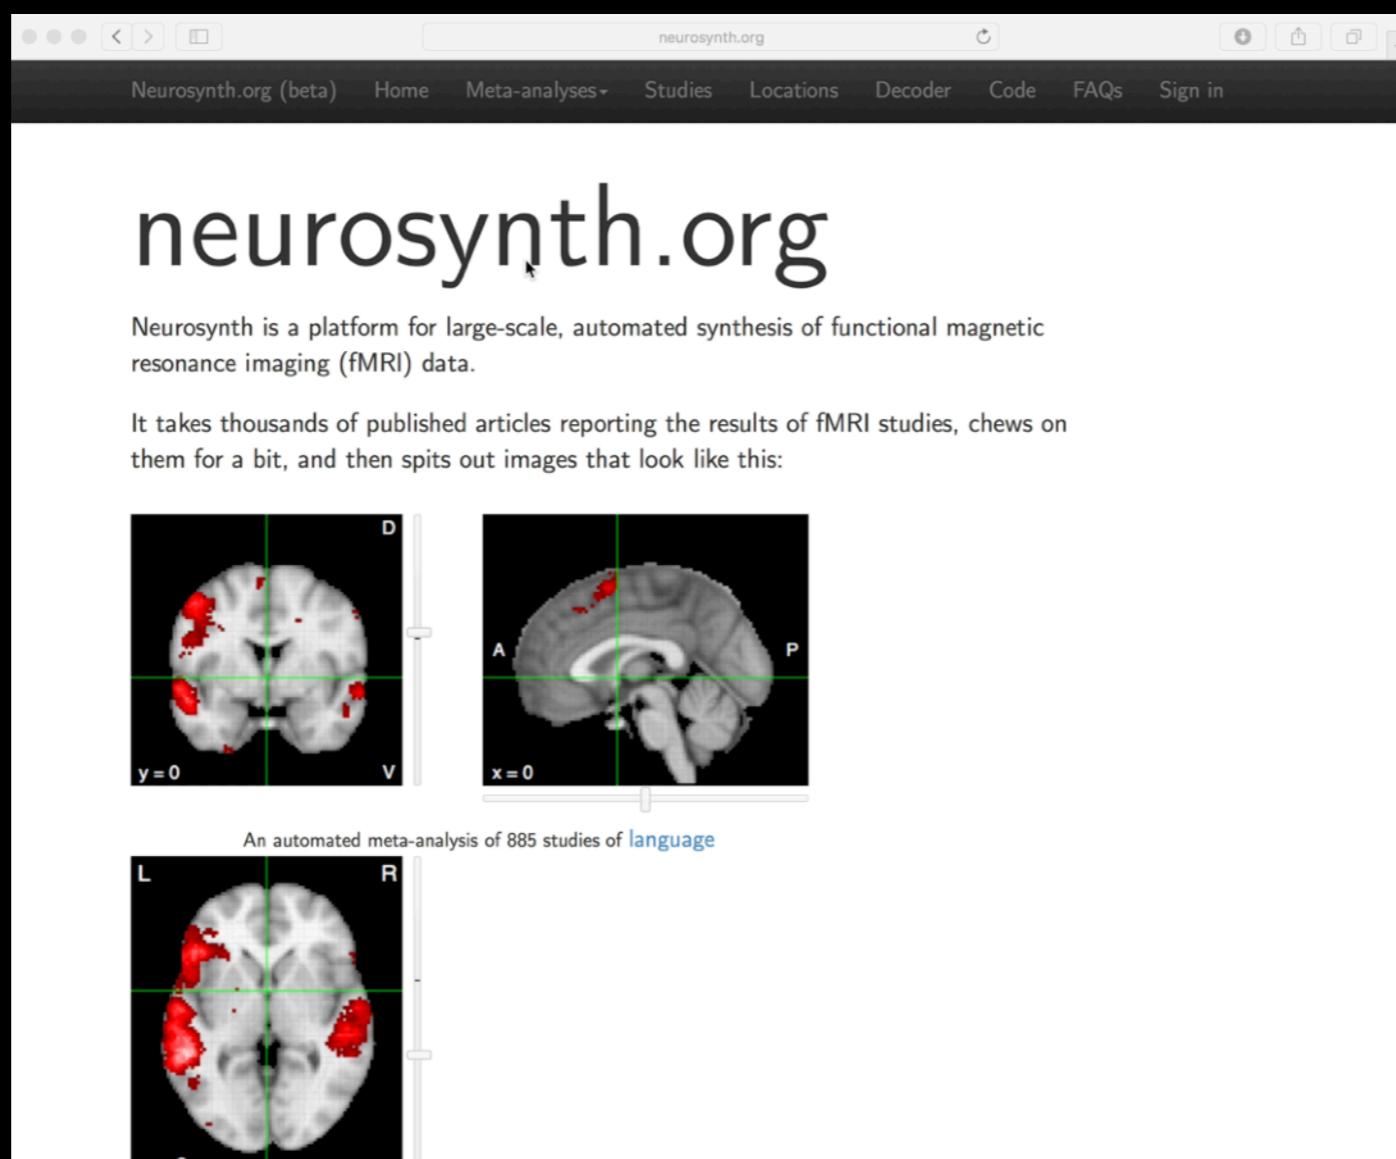

NEUROSYNTH

NEUROSYNTH

NEUROSYNTH

FORWARD AND REVERSE INFERENCE ARE NOW CALLED
"UNIFORMITY TEST" AND "ASSOCIATION TEST"

UNIFORMITY TEST -
IS THE VOXEL CONSISTENTLY ACTIVATED IN STUDIES THAT USE A TERM
VS UNIFORM

ASSOCIATION TEST -
IS ACTIVATION MORE CONSISTENT IN STUDIES THAT MENTION THE TERM
VS STUDIES THAT DON'T

NEUROSYNTH CURRENTLY COMPUTES THESE Z-SCORES VIA
FREQUENTIST TESTS.

FORWARD/INFERENCE LABELS ARE RESERVED FOR MAPS GENERATED
VIA BAYESIAN ESTIMATION. THE TWO SETS OF MAPS ARE RELATED BUT
DIFFERENT.

The dorsal anterior cingulate cortex is selective for pain: Results from large-scale reverse inference

Matthew D. Lieberman¹ and Naomi I. Eisenberger

Department of Psychology, University of California, Los Angeles, CA 90095-1563

Edited by Richard Ivry, University of California, Berkeley, CA, and accepted by the Editorial Board October 26, 2015 (received for review July 30, 2015)

Dorsal anterior cingulate cortex (dACC) activation is commonly observed in studies of pain, executive control, conflict monitoring, and salience processing, making it difficult to interpret the dACC's specific psychological function. Using Neurosynth, an automated brainmapping database [of over 10,000 functional MRI (fMRI) studies], we performed quantitative reverse inference analyses to explore the best general psychological account of the dACC function $P(\Psi \text{ process} | \text{dACC activity})$. Results clearly indicated that the best psychological description of dACC function was related to pain processing—not executive, conflict, or salience processing. We conclude by considering that physical pain may be an instance of a broader class of survival-relevant goals monitored by the dACC, in contrast to more arbitrary temporary goals, which may be monitored by the supplementary motor area.

dACC | pain | reverse inference | Neurosynth

Of all the regions in the brain that have received heavy study

To identify the psychological contributions of a region, reverse inference analyses, rather than forward inference analyses, are needed. Although reverse inference has been used as a derogatory term to characterize the error of using forward inference data to draw conclusions about a region's function ("that's just bad reverse inference"), appropriate reverse inference allows the desired inferences to be drawn. Reverse inference, refers to the probability that dACC activity is attributed to a particular psychological process, given the probability of a given psychological process, given activation $P(\Psi \text{ process} | \text{dACC activity})$.

Until recently, large-scale reverse inference analysis was difficult to carry out. Even popular multivoxel pattern analysis (MVPA) approaches are limited to reverse inference based on the specific tasks included in the study. For instance, a study of pain vs. no pain trials would likely show a positive predictive value for predicting future pain trials (15). However, such a study would not inform us

LETTER

The field of human neuroimaging has taken a particular shine to the ACC in the past two decades; if you've ever heard overheard some nerdy-looking people talking about "conflict monitoring", "error detection", or "reinforcement learning" in the human brain, there's a reasonable chance they were talking at least partly about the role of the ACC.

LETTER

Pain in the ACC?

Tor D. Wager^{a,b,1}, Lauren Y. Atlas^{c,d}, Matthew M. Botvinick^e, Luke J. Chang^f, Robert C. Coghill^g, Karen Deborah Davis^{h,i,j}, Gian Domenico Iannetti^k, Russell A. Poldrack^l, Alexander J. Shackman^{m,n,o}, and Tal Yarkoni^p

Lieberman and Eisenberger (1) claim that the "dorsal anterior cingulate cortex (dACC) is selective for pain." This surprising conclusion contradicts a large body of evidence showing robust dACC responses to nonpainful conditions. Electrophysiological and optogenetic studies have identified neuronal populations activated during foraging behavior, attention, emotion, reward expectancy, skeletomotor and visceromotor activity, and other functions (e.g., refs. 2–5). Only a small minority of dACC neurons are pain-related.

Lieberman and Eisenberger (1) later propose that the dACC responds to "enduring survival-relevant goals," including hunger and social rejection. This hypothesis appears inconsistent with selectivity for pain, with attention- (3) and motor-coding (4) dACC neurons, and with demonstrations of dissociable representations of pain and rejection in dACC (6). We agree that dACC subserves survival-relevant functions; however, acceptance of dACC as "pain-selective" will lead the field down the wrong track.

Lieberman and Eisenberger's (1) conclusions are based on Neurosynth.org (7), a database of activation coordinates and words used in >11,000 neuroimaging studies. The claim of pain selectivity is based on a statistical preference

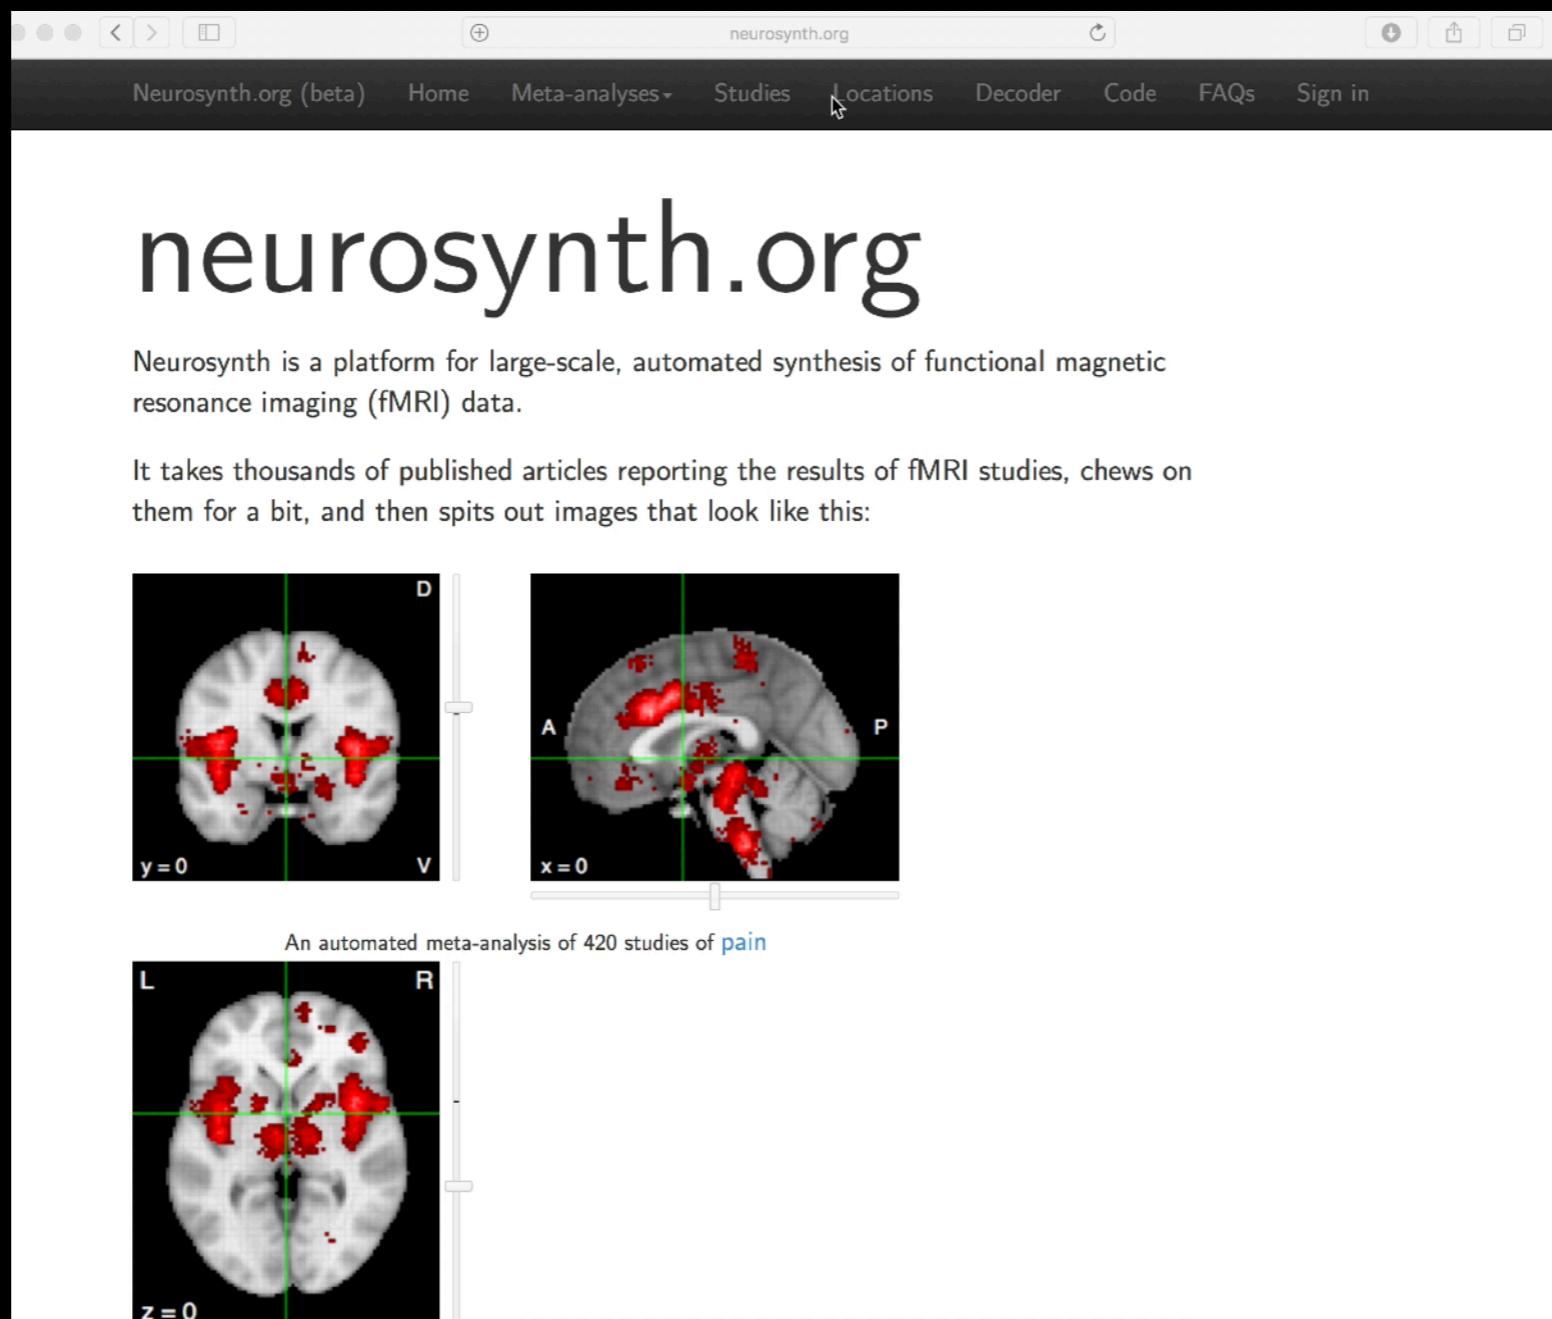

Nonetheless, Lieberman and Eisenberger (1) wrote that the "best interpretation of dACC activity is in terms of pain . . .," implying that dACC activity can be used as an indicator for pain and/or related survival-relevant functions. This sets a dangerous precedent, and would yield erroneous conclusions in many instances (Fig. 1A). In addition, Lieberman and Eisenberger's claims of selectivity are based on a flawed method of making "reverse inferences" (RI), inferences based on the posterior probability of a mental state (S) given regional fMRI activation. Valid RI requires estimating the probability of S given activation using Bayes' rule. Unlike prior metaanalyses testing RI (e.g., ref. 7), Lieberman and Eisenberger's analyses do not do this. Rather, they use a nonstandard comparison of Z-scores for pain with other individual keywords. This has been extensively critiqued elsewhere (www.talyarkoni.org/blog/2015/12/14/still-not-selective-comment-on-comment-on-lieberman-eisenberger-2015/) and is not equivalent to estimating posterior probabilities. In fact, using the same database, we estimate the probability of a study inducing physical pain given activity in pain-selective dACC at ~12%, on par with language, emotion, attention, and memory (Fig. 1B).

And while I'll be the first to admit that I know very little about the anterior cingulate cortex, I am probably the world's foremost expert on Neurosynth*—because I created it.

I also have an obvious interest in making sure that Neurosynth is used with appropriate care and caution.

In what follows, I provide my HIBAR reactions to the Lieberman & Eisenberger (2015) manuscript, focusing largely on whether L&E's bold conclusion is supported by the Neurosynth findings they review (spoiler alert: no).

MACM

PAULI

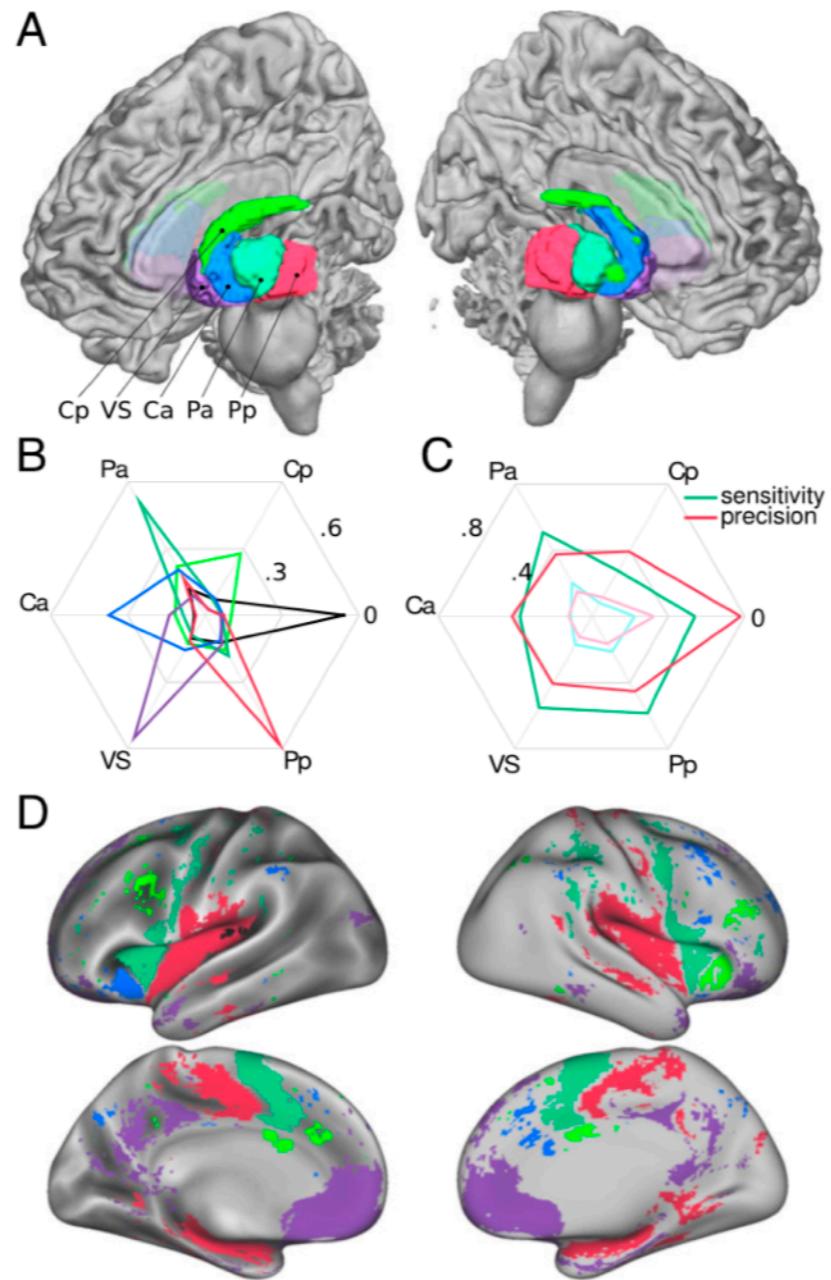

Fig. 1. (A) Cluster analysis (k -means, $k = 5$) of corticostriatal coactivation patterns across imaging studies identified distinct striatal zones. The five zones showed strong bilateral symmetry. Symmetry analysis is shown in *SI Appendix, Fig. S3*, and results with different values of k are shown in *SI Appendix, Fig. S4*. (B) Based on the pattern of reported cortical activation, a naive Bayes classifier predicted which striatal zone was the most active one. The confusion matrix, shown as a polar plot, indicates the probability that the classifier predicted activation in the correct zone and the probability that it incorrectly predicted activation in one of the other zones. Category “0” represents studies with no striatal activation (i.e., no active zone). (C) Sensitivity (dark green) and precision (i.e., positive predictive value, dark red) of the classifier for each functional zone. Attenuated colors (light green and red) indicate chance performance levels in the permutation test. Actual performance exceeded chance levels substantially for each category. (D) Maximum a posteriori estimates from the naive Bayes classifier indicate which striatal zone is most strongly coactivated with each cortical voxel ($q < 0.05$, false discovery rate-corrected).

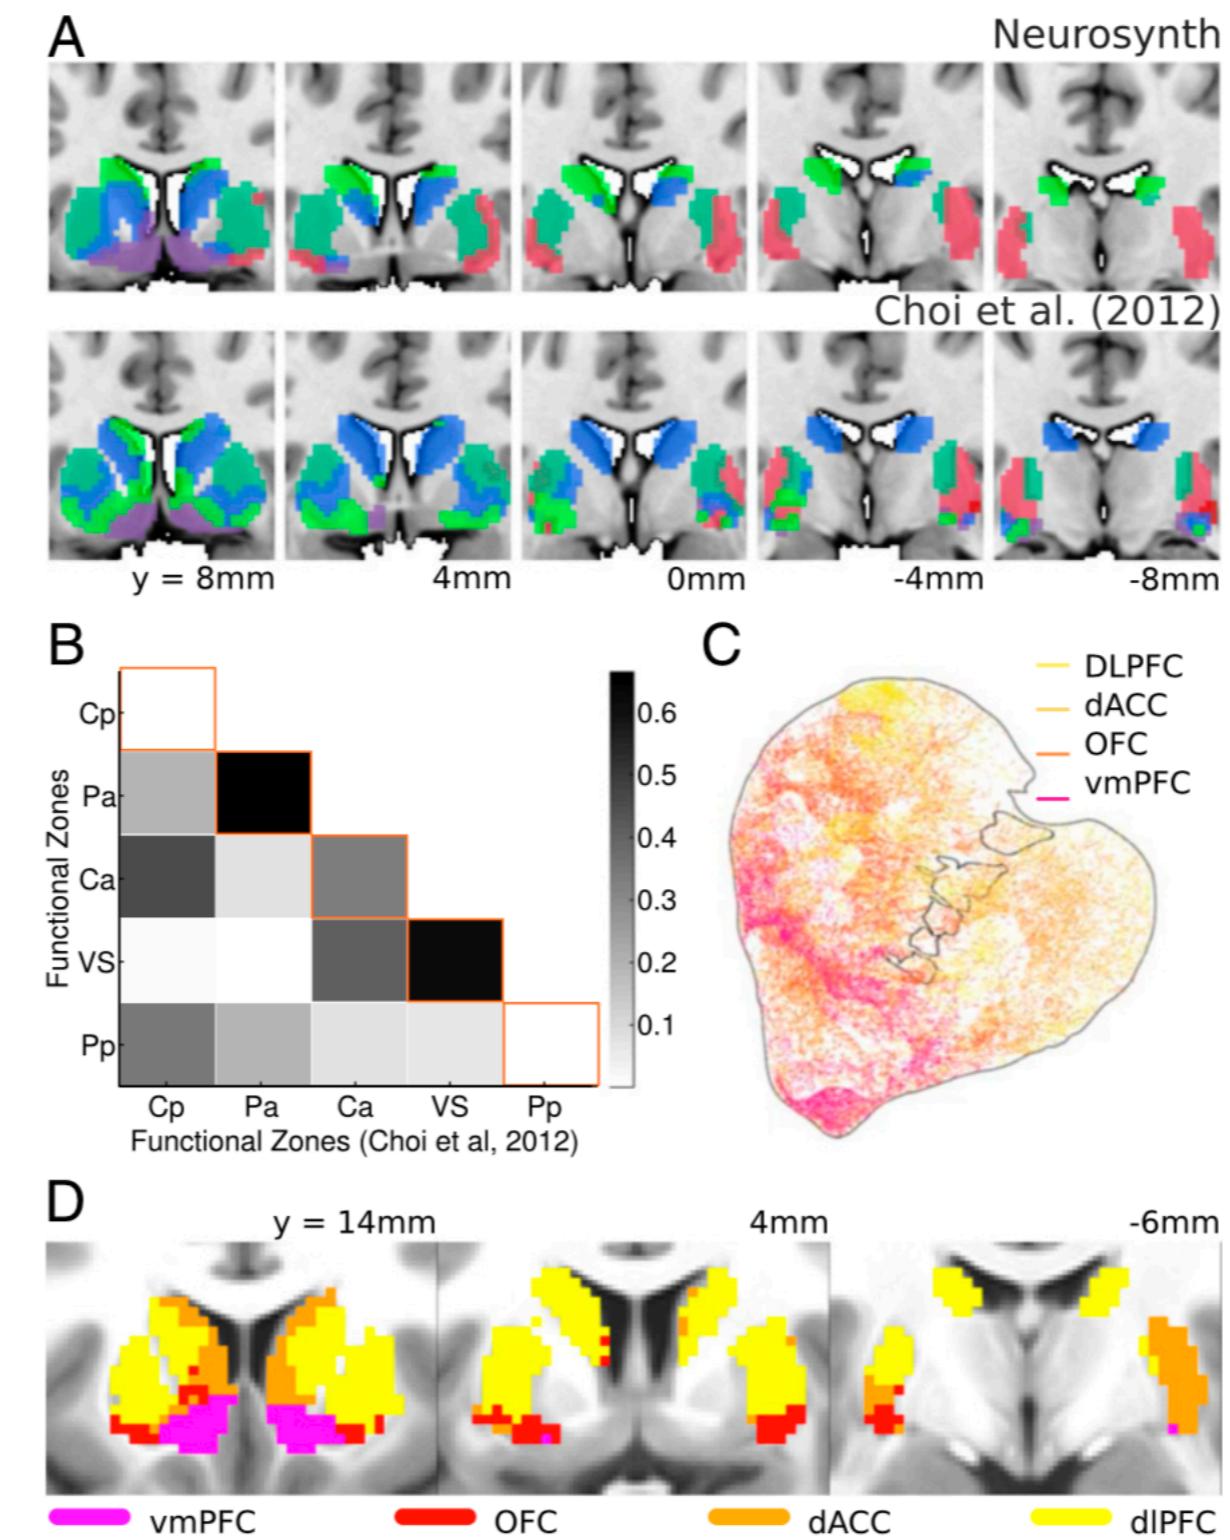

Fig. 2. (A) Side-by-side comparison of our parcellation with an existing $k = 7$ striatal parcellation (17), based on RSFC, indicates that the two approaches only lead to moderately overlapping results. (B) Dice's coefficients of a zone-by-zone comparison of our results with the existing solution. (C) Recent anterograde tracer study in nonhuman primates found strong evidence for a gradient of frontal cortical-striatal axon projections (26). dIPFC, dorsolateral PFC. (D) Analysis of coactivation of each striatal voxel with the different regions of interest in C, defined here based on the AAL atlas (61), show a similar pattern in humans. Reprinted from ref. 26.

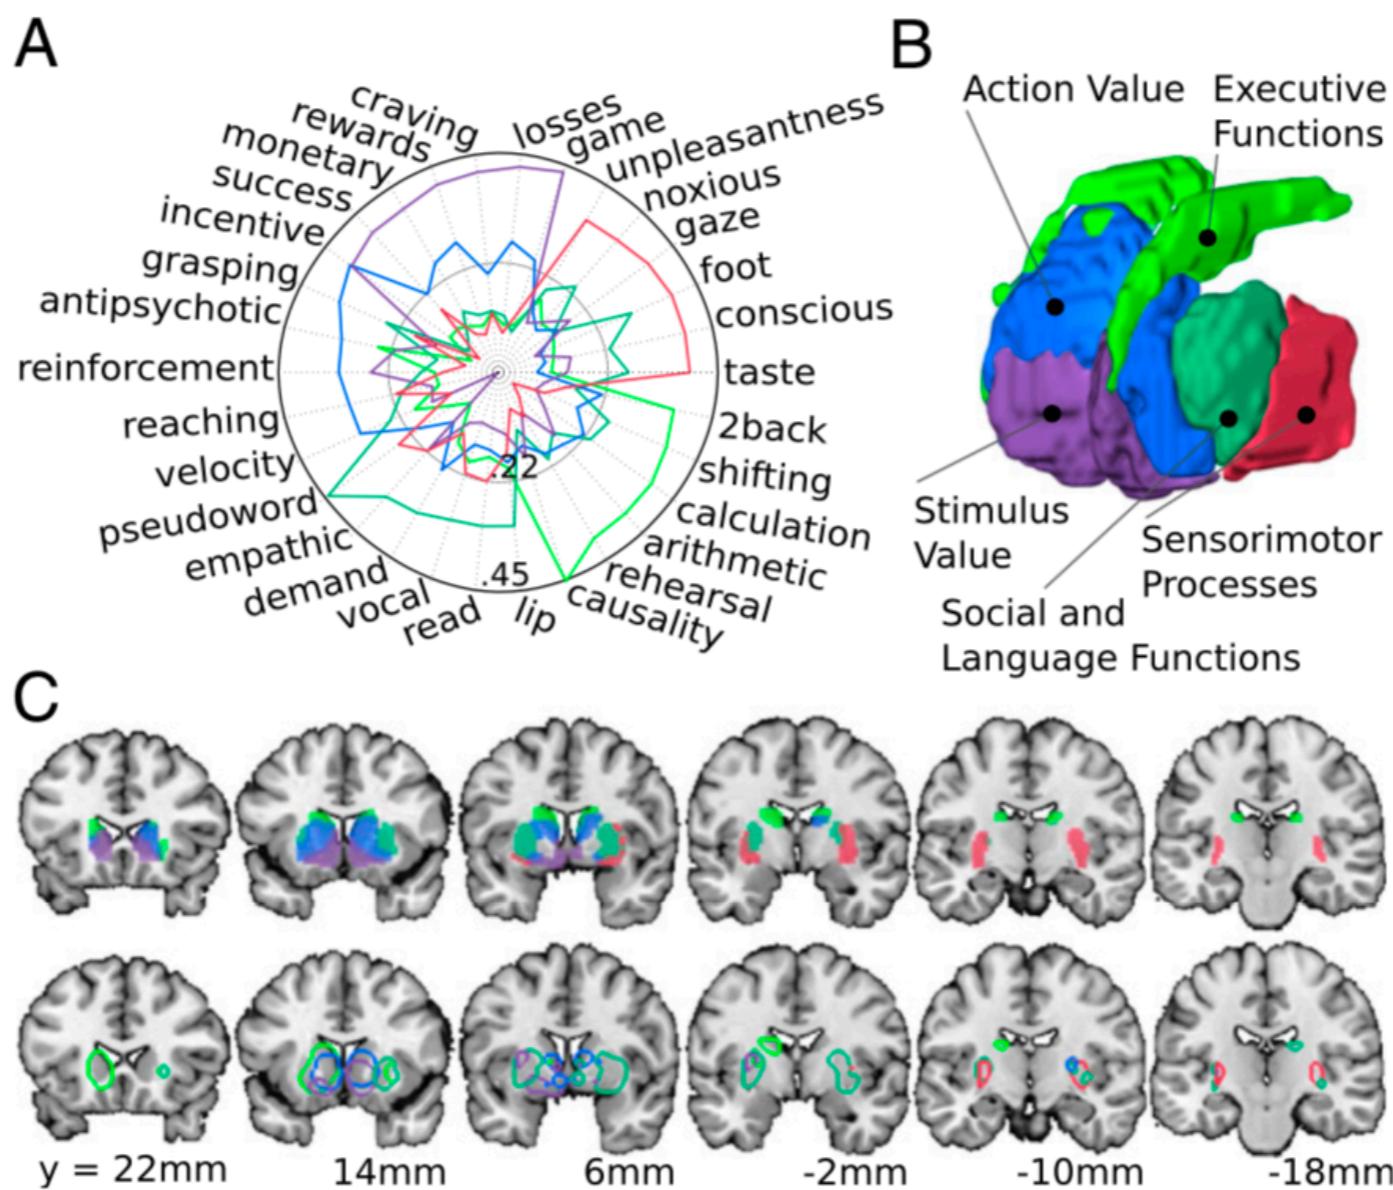

Fig. 3. To identify the psychological functions associated with each striatal zone, we calculated for each psychological term included in the NeuroSynth database its likelihood ratio of appearing in a study, given that activation was reported anywhere within a zone. (A) Distribution of likelihood ratios across functional zones indicates a clear functional dissociation. (B) Subjective summary of the main psychological function of each functional zone in a working model. (C) Based on the reported striatal activation and the occurrence of psychological terms in each study, it was possible to identify the most representative studies for each functional zone. The striatal zones identified in our coactivation analysis (*Top*) and a reconstructed outline of the activation reported in the representative studies (*Bottom*) are shown.

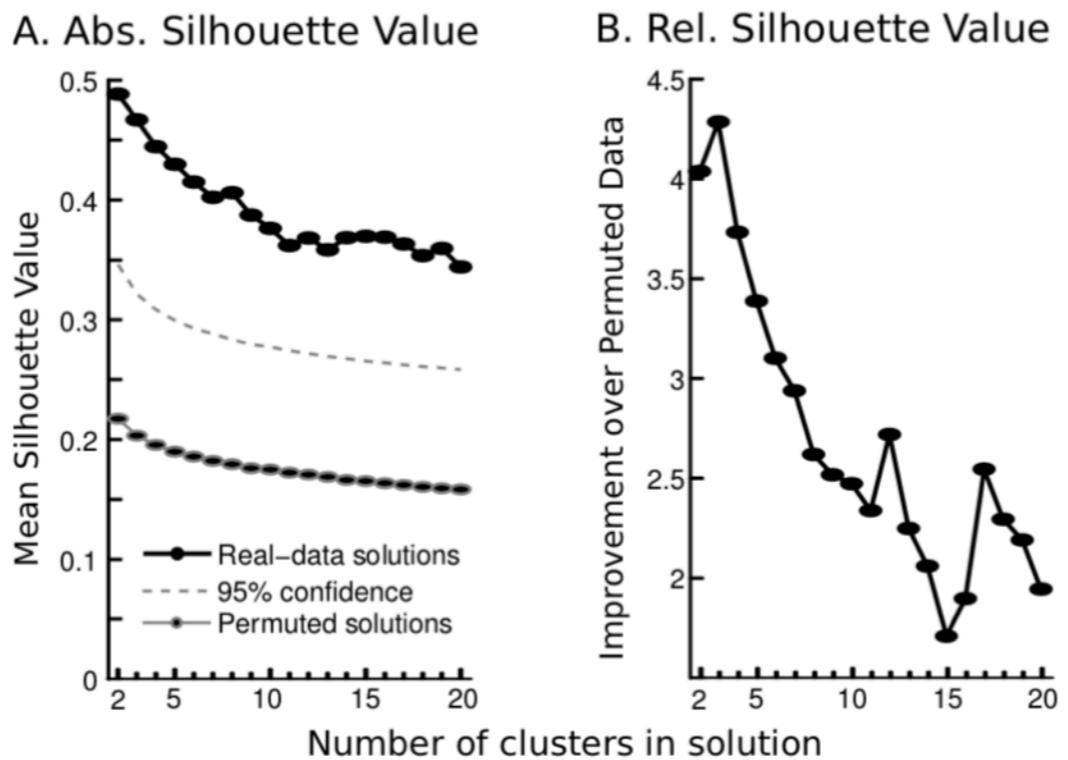

Fig. S1. In terms of cluster quality, none of the 19 cluster solutions ($k=2-20$) emerged as a clear winner, but all solutions were clearly better than chance. To assess cluster quality, we used Monte-Carlo simulations to establish statistical significance against a null hypothesis that the clusters are randomly distributed across striatal voxels. For this purpose the columns in the striatal voxel (rows) by cortical voxel (columns) correlation matrix were permuted, k-means was run on that permuted correlation matrix, and the silhouette value was calculated [8]. We used a minimum of 134 permutations for each cluster solution, and found that this resulted in a very stable estimate of cluster quality.

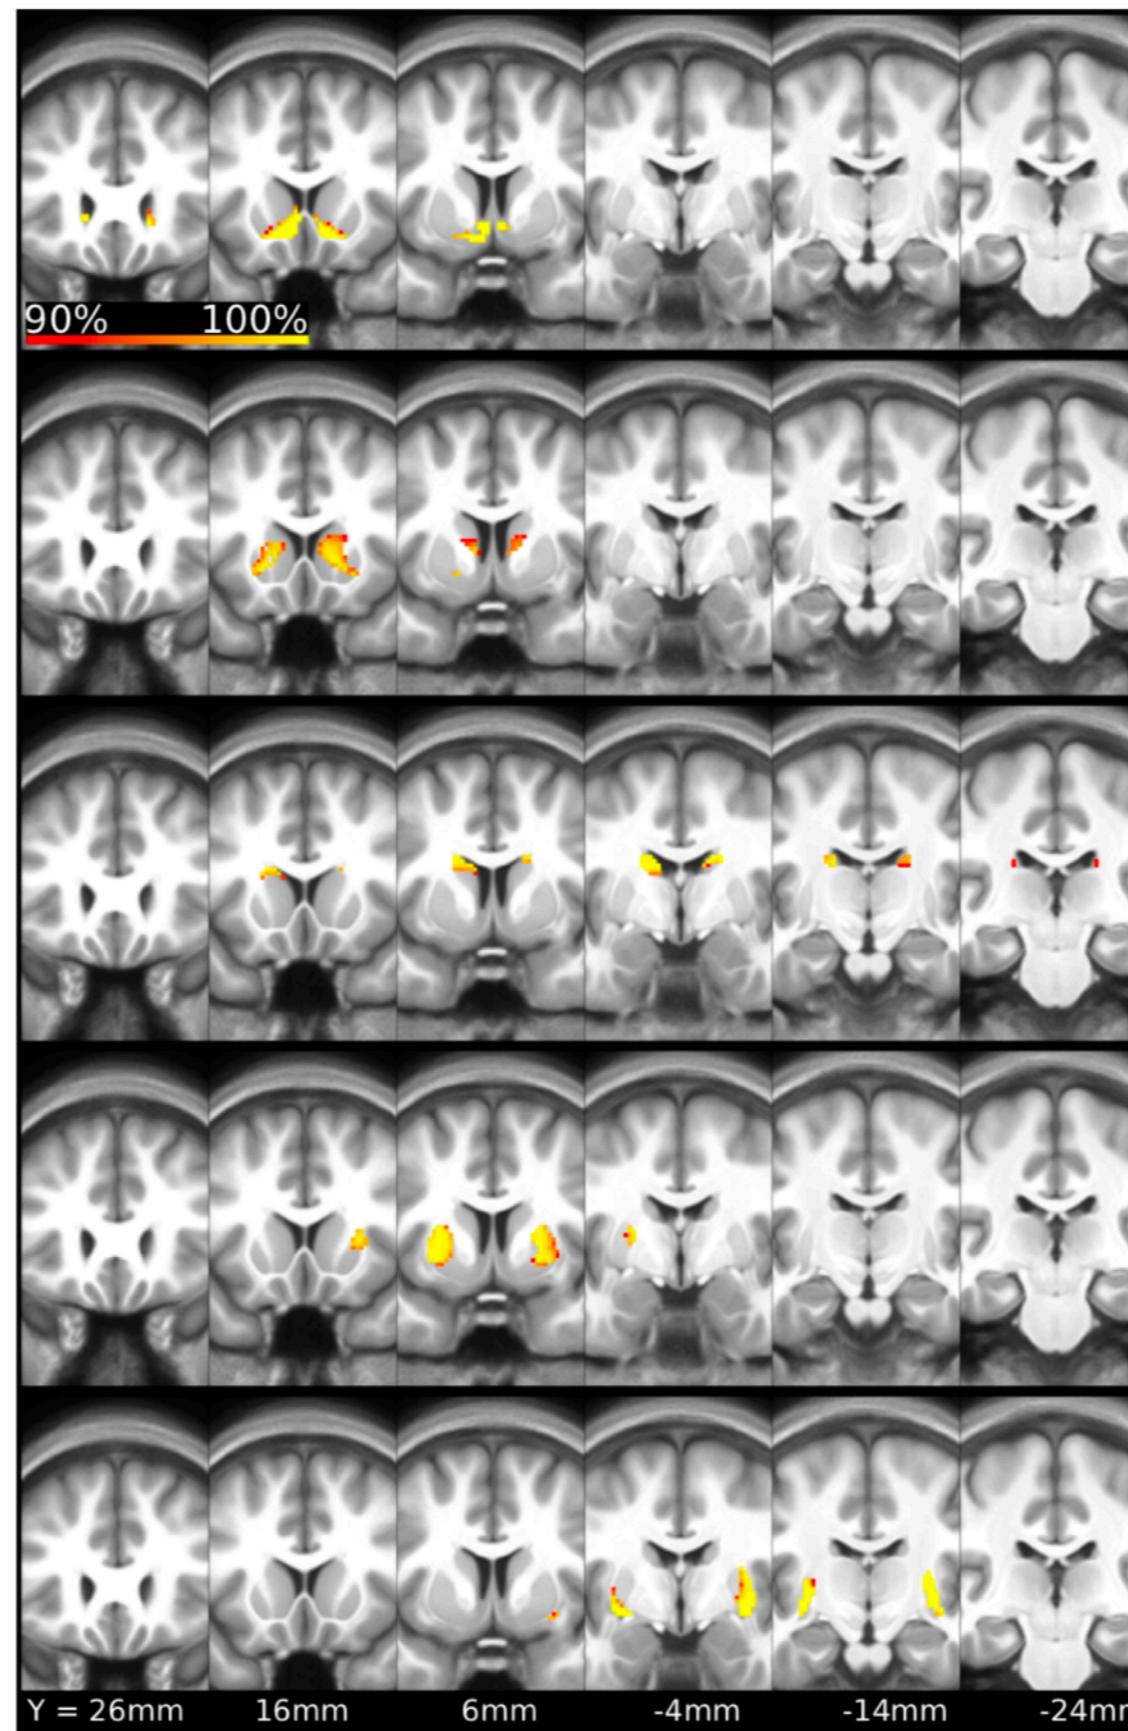

Fig. S2. Probabilistic maps of our five-cluster solution. Probabilistic maps were created by drawing 1000 bootstrap samples of the studies included in the database. Probabilities reflect the likelihood that a voxel was assigned to the same striatal zone across bootstrap samples (see Supplementary Information “Naïve Bayes classifier”). For example, if a voxel was assigned to the same striatal zone by the cluster analysis (after clusters were matched across bootstrap samples using nearest-neighbor similarity assessed by Dice’s coefficient) in 998 of the 1000 bootstrap samples, this would yield a probability of 99.8%. The average Dice coefficient between these 1000 solutions and the solution reported in the manuscript was 0.89 ($SD=0.048$).

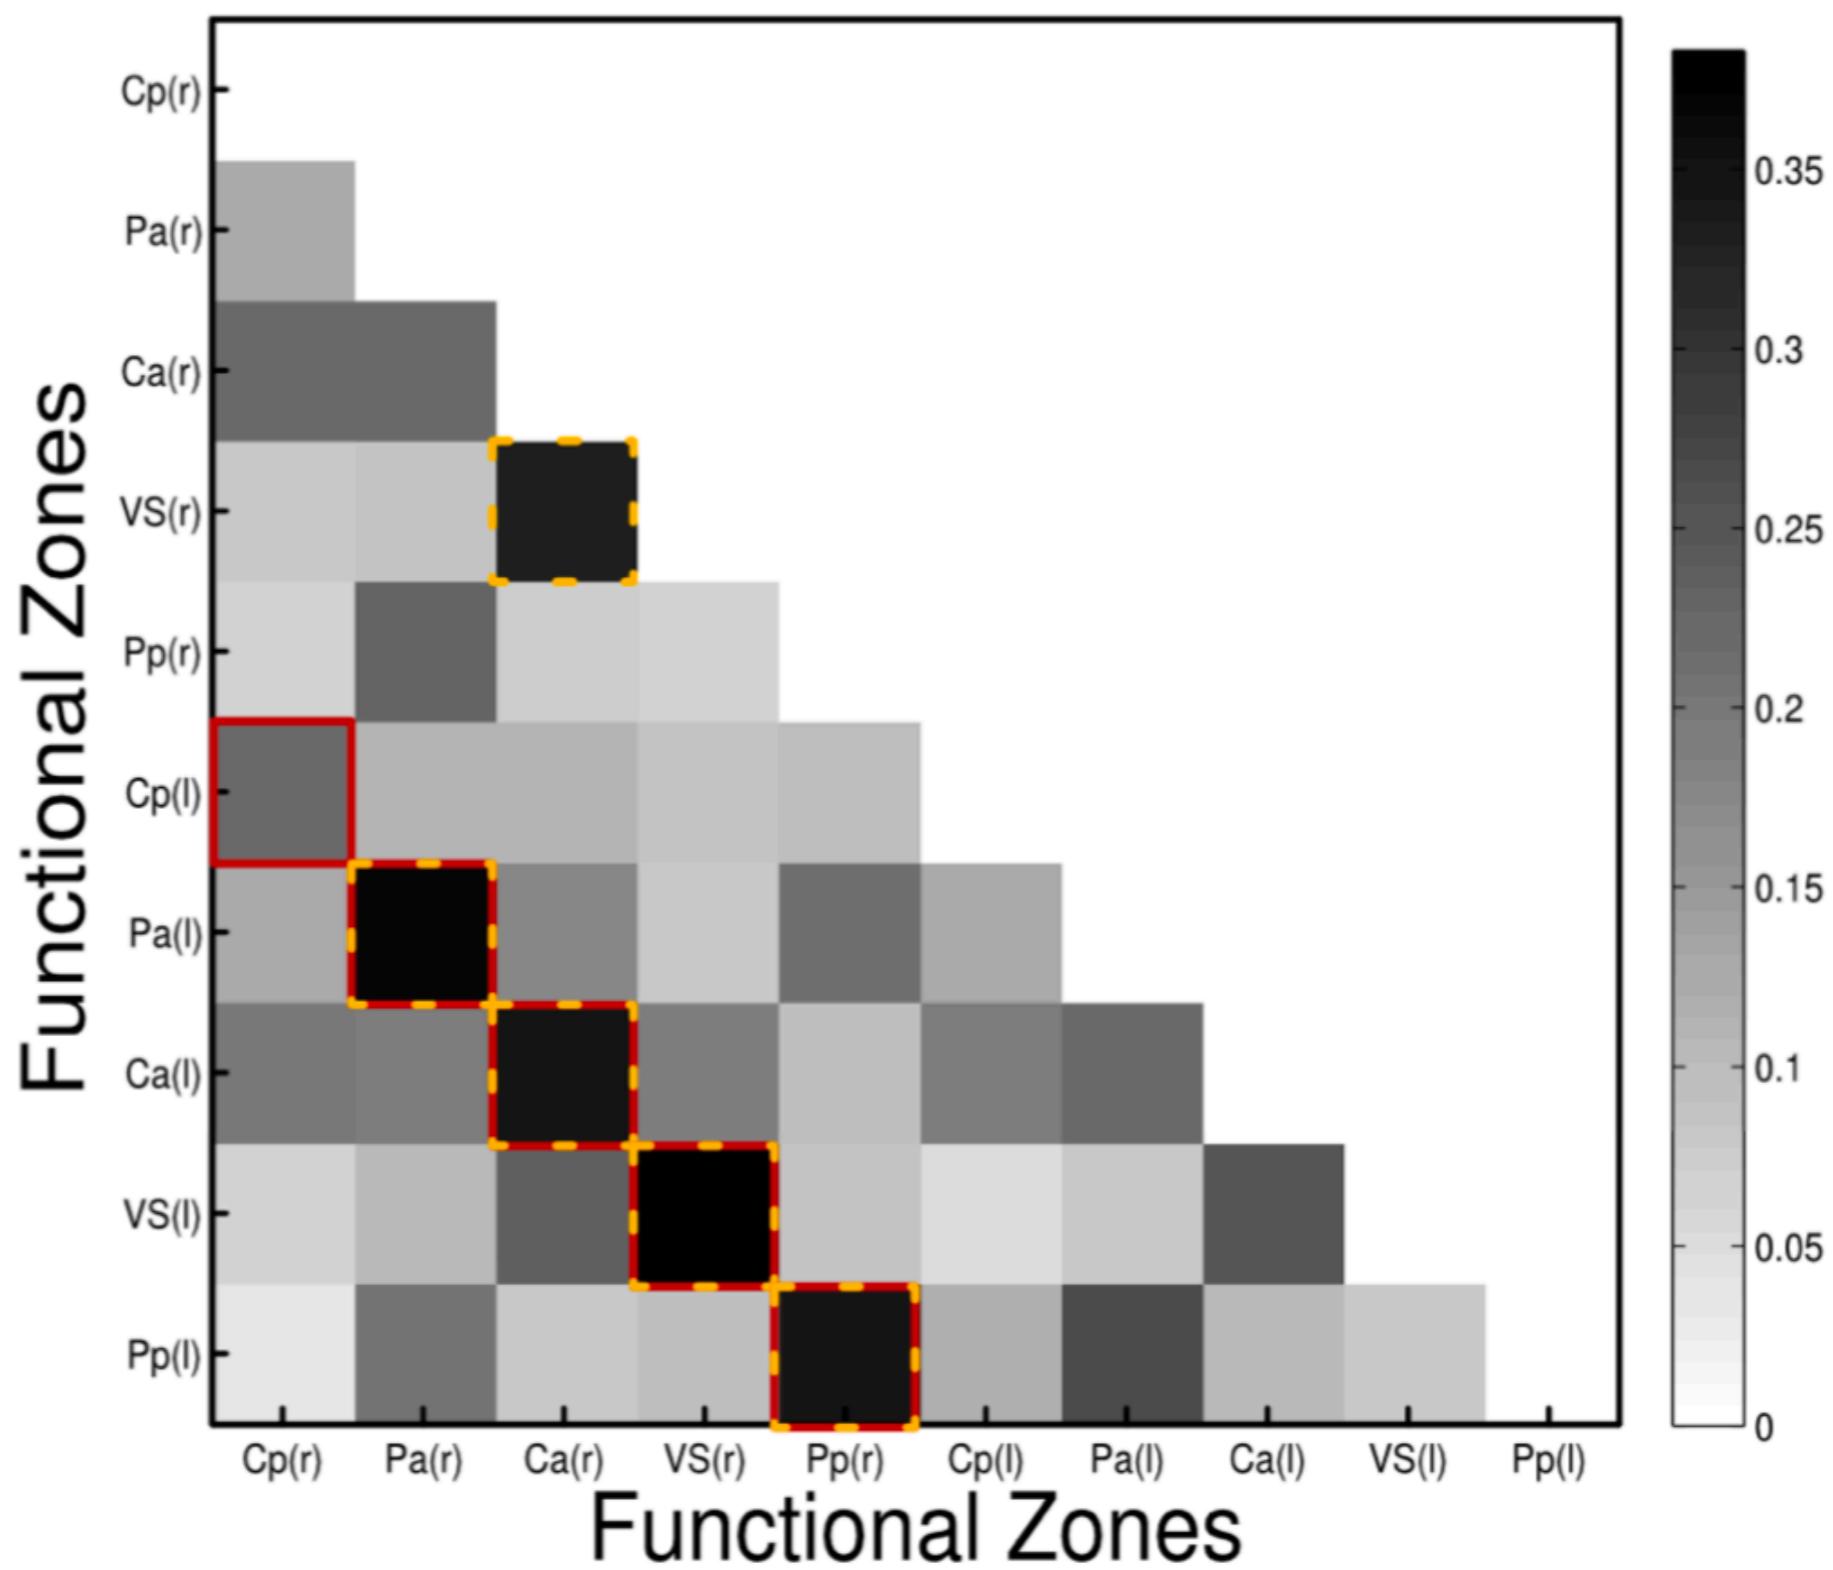

Fig. S3. To evaluate hemispheric symmetry of each functional zone, we evaluated for each zone how strongly its activation (proportion of active voxels within zone) in one hemisphere correlated with the same zone in the opposite hemisphere, and with all other zones in the same and opposite hemisphere.

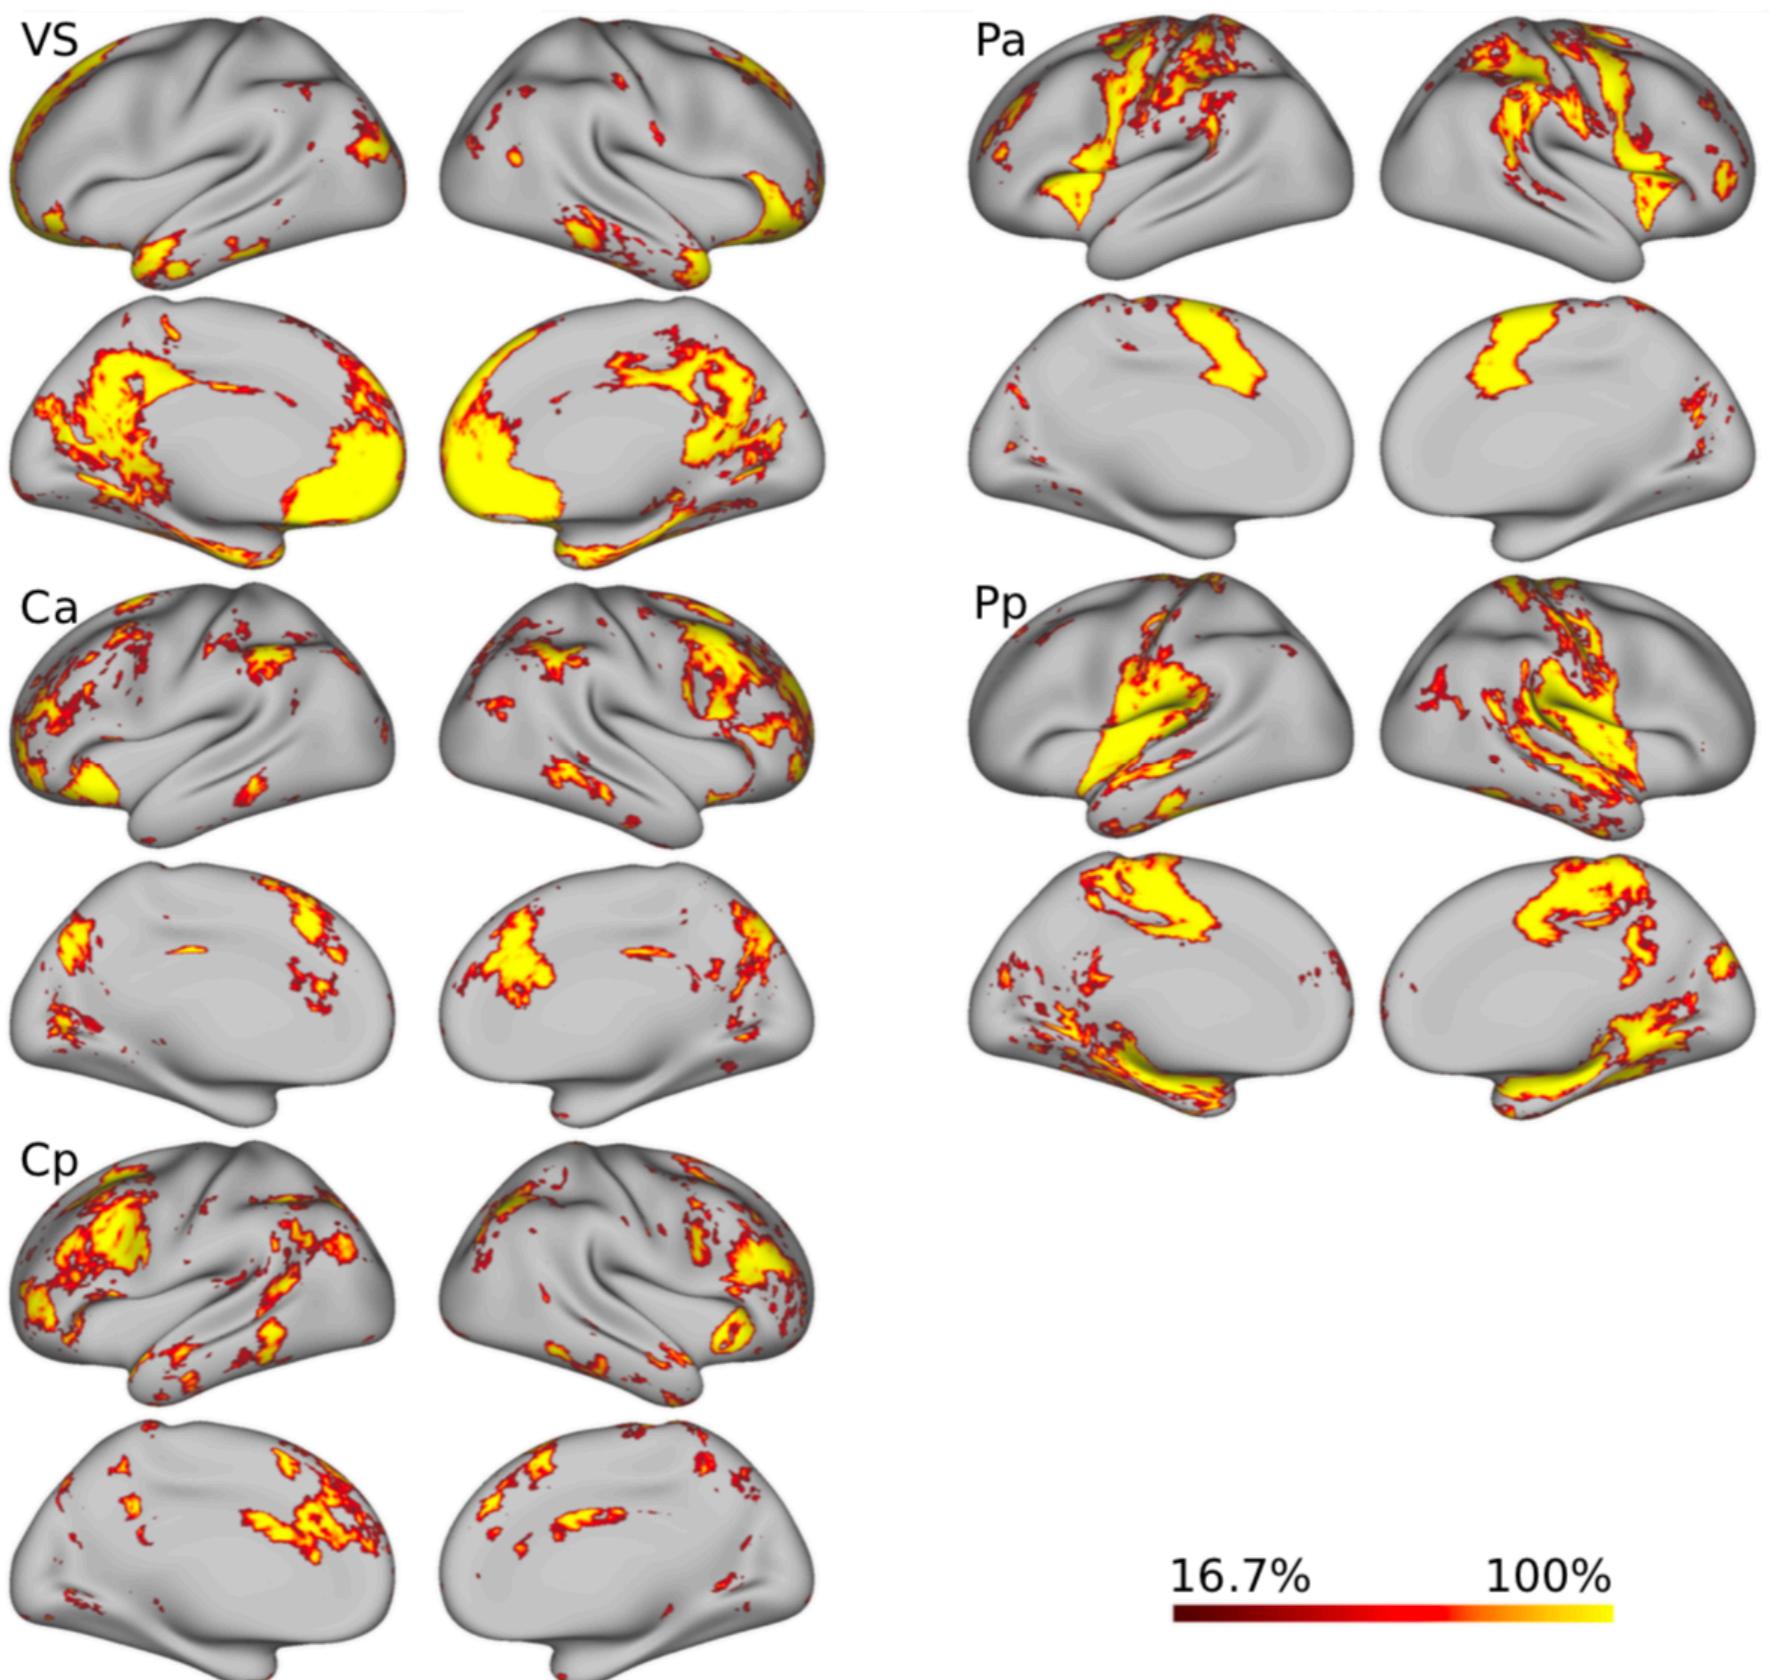

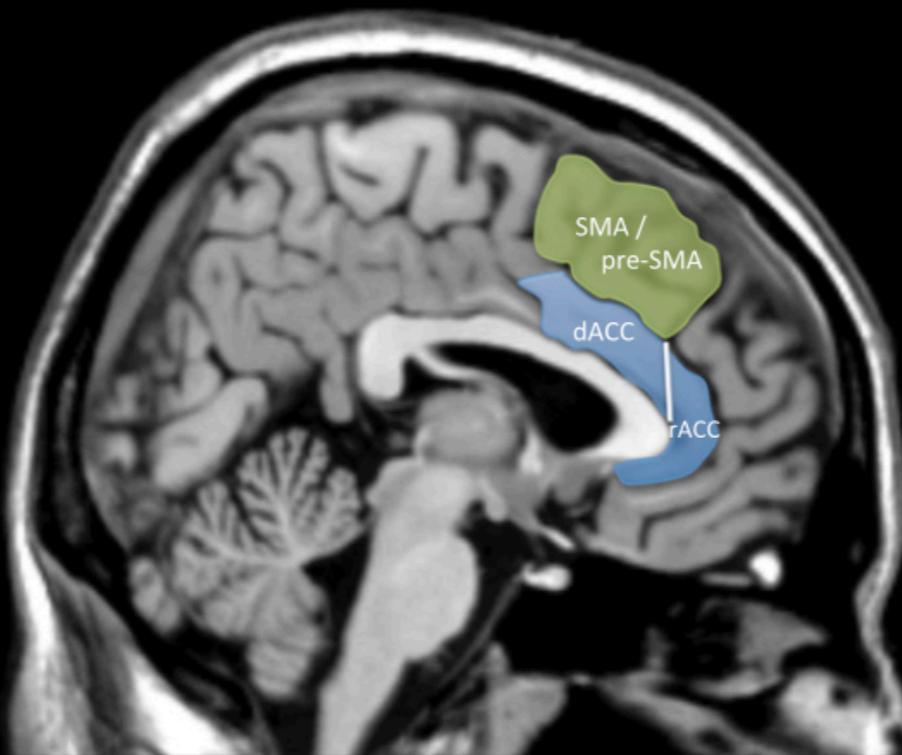

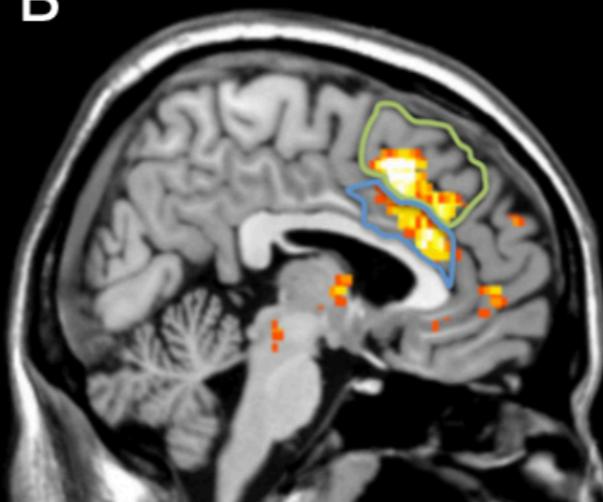

Fig. S5. Maximum a posteriori (MAP) estimates of how reliably a cortical voxel was co-activated with the different functional zones. MAP estimates were determined by drawing 1000 bootstrap samples from the studies included in the database, and training a naïve Bayes classifier to predict which striatal is reported to be the most active in each study, based on the pattern of reported cortical activation. In a final step, we counted for each voxel, how often it would be more strongly associated with one striatal zone, than with any other striatal zone.
